## ABSTRACT

In the last decades, energy-efficient road transportation has become one of the major concerns of many countries worldwide. Governmental regulation standards are progressively strict with respect to the maximization of vehicle fuel economy as well as the mitigation of tailpipe emissions. In this scenario, the automotive industry has been providing potential alternatives to address this current issue. One of those possible solutions is the start/stop (SS) system, which consists of an engine shutdown strategy that prevents idling operation. Vehicle idling results in a relevant fraction of fuel consumption and air pollutant emissions, especially in urban driving conditions. Therefore, this study aims to simulate a SS system in an internal combustion engine vehicle model in order to evaluate its improvements in fuel consumption and reduction of generated tailpipe gases. The vehicle simulation model is developed in Matlab/Simulink™ environment and the exhaust emissions are quantified by the ADVISOR™ fuel converter block. For a further analysis that takes into account different driving conditions, the vehicle will be analyzed under the FTP-75 driving cycle used in emission evaluation procedure and also under a real-world driving cycle.

**Keywords:** Start/stop system, fuel consumption, exhaust emissions, ADVISOR, vehicle idling

## INTRODUCTION

Air quality improvement policies have increasingly become a trend worldwide due to the hazardous effects air pollution has caused to human health and environment. In the Paris agreement [1], [2], many countries (including Brazil) have committed to implement several measures for the reduction of their high gas emission indexes. Furthermore, energy security is another important goal established by authorities through demanding governmental regulations that are able to generate more sustainable cities.

In this scenario, automotive industry plays an important role to address such concern as internal combustion engine vehicles contribute significantly to the urban air pollution and consequent environmental impacts [3], [4] and require a huge amount of fossil fuel resources [5], which are predicted to be considerably lower in about two decades if the oil consumption still follows the current rate [6], [7]. Miao et al. [8] present a study case of gas emissions in China and explain that nitrogen oxides (NO<sub>x</sub>) are of major concern due to the fact that they are one of the most dangerous gases for large amounts constantly released in the atmosphere. In their work, they show that the road transportation activity is one of the main contributors to the emission of such toxic gas. Besides, several studies have presented that motor vehicle emissions are directly associated to different ecosystem and people's health damages [9]–[11].

Thus, researchers have extensively discussed about innovative systems and vehicle-based modifications that can provide low-emission and fuel-efficient vehicles. Such alternatives include vehicle redesign with lighter-weight materials [12], devices for aerodynamic drag reduction [13], tire design to decrease rolling resistance [14], [15], drivetrain design improvement [16], [17] and engine downsizing [18]. Moreover, studies have shown that an optimum gear shifting control results in significant reduction of gas emissions and vehicle fuel consumption [19]–[21]. Hybridization is another appealing alternative to achieve better fuel economy and emission indexes [22], [23].

One of those attractive solutions with reasonable price is the start/stop (SS) system, which can mitigate exhaust emissions as well as fuel consumption by switching off the engine automatically when no propulsion is requested by the driver. Since the engine idling condition consists of a relevant amount of fuel consumed and air pollutant emissions [24], SS technology, which prevents such idle periods, has increasingly been used in automotive manufactures such as Nissan [25], Ford [26], General Motors [27], BMW [28], and others.

Previous works have proposed SS strategies for hybrid vehicles in order to increase mileage and reduce gas emissions [29], [30]. For their SS controllers, different input parameters are considered (e.g. required torque, vehicle speed, battery state-of-charge etc.) and the engine is turned off as long as the driving conditions meet all the SS strategy constraints. Furthermore, Bishop et al. [31] implement a belt-driven starter/alternator into a GMC Envoy to assist the start/stop management of its 4.2L six-cylinder engine. Their study obtains the fuel consumption reduction of 5.3% and 4.0% in urban and highway driving cycles, respectively. Wishart et al. [32] carry out dynamometer and fleet tests to evaluate the benefits of the implementation of idle-stop (IS) systems in passenger vehicles for different driving cycles, achieving the fuel economy improvement of 6.3% (NEDC cycle) and 7.1% (JC08 cycle) for the Volkswagen Golf as well as 8.3% (NEDC cycle) and 7.0% (JC08 cycle) for the Mazda 3. With respect to greenhouse gases, Fonseca et al. [33] present a substantial decrease of such emissions with the integration of SS technology on a four-wheel-drive diesel vehicle. In another approach, scientists have investigated the effective idle stop or break-even point [28], [34]–[37], that is, the minimum time the engine has to be switched off to generate higher fuel saving than the energy needed to restart the engine. In published literature, it is possible to infer that idle time of less than 3 s usually results in ineffective engine stop [28].

In this paper, a SS system is simulated for a conventional vehicle equipped with 1.0L 4-cylinder gasoline engine. The vehicle model runs under the urban FTP-75 and real-world (Campinas city) driving cycles so that fuel consumption and air pollutant emission indexes' improvements can be evaluated. Such exhaust emissions are measured according to the ADVISOR<sup>TM</sup> fuel converter block and the model is simulated in Matlab/Simulink<sup>TM</sup> environment.

## LONGITUDINAL VEHICLE DYNAMICS

In this paper, the longitudinal vehicle modeling is introduced according to the governing equations, as proposed by Gillespie [38]. In addition, the maximum tire-ground and clutch transmissible torque constraints [19] are incorporated in the vehicle model. Figure 1 illustrates the resistive forces the vehicle is subject to during motion.

Figure 1 – Free-body diagram of vehicle adapted from [21]

The required torque  $T_{rw}$  [Nm] can be calculated by Equation 1, as a function of tire dynamic radius  $r$  [m], the inertia force (vehicle mass  $M$  [kg] and required acceleration  $a_{req}$  [m/s<sup>2</sup>]), rolling resistance  $R_x$  [N], aerodynamic drag  $D_A$  [N] and climbing resistance (vehicle weight  $W$  [N] and road angle  $\theta$  [°]). The latter is only considered in the model running on the real-world driving cycle based on Campinas city. For the standard FTP-75 drive cycle, the gravitational force is not taken into account as the road grade is assumed as null.

$$T_{rw} = (M a_{req} + R_x + D_A + W \sin(\theta)) r \quad (1)$$

The aerodynamic drag  $D_A$  [N] is due to the wind resistance and opposes to the vehicle motion. Such resistive force is dependent upon vehicle body geometry and air properties and can be determined by Equation 2, where  $\rho$  [kg/m<sup>3</sup>],  $C_d$  and  $A$  [m<sup>2</sup>] are the air density, drag coefficient and frontal area of the vehicle, respectively. Besides,  $D_A$  varies directly as the square of the vehicle speed  $V$  [m/s].

$$D_A = 0.5 \rho V^2 C_d A \quad (2)$$

The rolling resistance  $R_x$  [N], on the other hand, is given by the energy loss generated by road-tire interface. This load is of great importance at low speeds and can be expressed by Equation 3.

$$R_x = 0.01 \left( 1 + \frac{2.24V}{100} \right) W \quad (3)$$

With respect to the dynamic radius  $r$ , it is defined as a function of the geometric radius  $r_g$  and the correction factor  $k_v$ , which is influenced by the vehicle speed.

$$r = 0.98 r_g (1 + 0.01 k_v) \quad (4)$$

The speed profile provided by the analyzed driving cycles (FTP-75 and Campinas city) is the target speed. The required acceleration for the model is then calculated according to the difference between the desired speed  $V_d$  at the next time step  $(t + \Delta t)$  and actual speed  $V$  at the current simulation time  $t$ , divided by the time step  $\Delta t$  itself, as shown in Equation 5.

$$a_{req}(t) = \frac{V_t(t + \Delta t) - V(t)}{\Delta t} \quad (5)$$

Once determined the required torque for the vehicle model, it is possible to calculate the respective engine required torque  $T_{ICE}$  [Nm], expressed by Equation 6, as a function of the engine inertia  $I_e$  [kgm<sup>2</sup>], gearbox inertia  $I_t$  [kgm<sup>2</sup>], differential inertia  $I_d$  [kgm<sup>2</sup>], wheels and tires' inertia  $I_w$  [kgm<sup>2</sup>], differential gear ratio  $N_d$ , transmission gear ratio  $N_t$  and overall powertrain efficiency  $\eta_{td}$ .

$$T_{ICE} = \frac{T_{rw} + ((I_e + I_t)(N_t N_d)^2 + I_d N_d^2 + I_w) \frac{a_{req}}{r}}{N_t N_d \eta_{td}} \quad (6)$$

However, such delivered torque by the engine should be limited to its maximum (wide-open throttle) torque curve, as depicted by Figure 2. For conditions  $T_{ICE}$  is greater than the maximum engine torque  $T_{ICE}^{max}$  at certain speed, the former is limited by the value of the latter.

Figure 2 – Wide-open throttle engine torque curve [20], [22]

Furthermore, during the gear shifting, the clutch is another limiting factor for the available gearbox input torque. This happens due to the fact that the engine is not able to deliver the same amount of required torque  $T_{ICE}$  since the ICE decouples from the transmission [39]. Thus, the clutch transmissible torque  $T_{CL}$  is determined by Equation 7, as proposed by Kulkarni, Shim and Zhang [40], according to its friction coefficient  $\mu_{cl}$ , external  $R_o$  and internal  $R_i$  disks' radii [m] and number of faces  $n$ . For the simulation model, the gear shifting process was introduced based on the procedure defined in [20], [21]. The time of 0.3 s was assumed for the ICE decoupling from the gearbox, followed by the posterior gear shifting during 0.2 s and, finally, the gradual clutch recoupling, which occurs for 0.5 s. The clutch spring force  $F_n$  [N] varies according to the pedal position, as presented in Figure 3.

$$T_{CL} = \frac{2}{3} \mu_{cl} F_n n \frac{R_o^3 - R_i^3}{R_o^2 - R_i^2} \quad (7)$$

The gearbox input torque  $T_{gb}$  is then given by the minimum value among the engine required torque  $T_{ICE}$ , maximum engine torque  $T_{ICE}^{max}$  and the clutch transmissible torque  $T_{CL}$ , as described by Equation 8. The available torque transferred to the wheels, on the other hand, can be calculated by Equation 9, as a function of the parameters described previously.

Figure 3 – Clutch spring force behavior along clutch pedal position variation [20], [22]

$$T_{gb} = \min \{T_{ICE}, T_{ICE}^{max}, T_{CL}\} \quad (8)$$

$$T_w^{av} = T_{gb} N_t N_d \eta_{td} - ((I_e + I_t)(N_t N_d)^2 + I_d N_d^2 + I_w) \frac{a_{req}}{r} \quad (9)$$

In addition, the tire traction limit is another condition that eventually reduces vehicle performance as a result of tire slipping. To address such issue, in this study, the tire-ground transmissible torque  $T_{tg(max)}$  model (Equation 10), as described by [41], is considered as a constraint in the determination of the effective torque delivered to the wheels  $T_w^{eff}$ , which can be expressed by Equation 11.

$$T_{f(max)} = \mu \left( \frac{Wc}{2L} - \frac{Wha_x}{2Lg} \right) \quad (10)$$

Where:

$L$  = Wheelbase [m]

$h$  = Height of the vehicle's center of gravity [m]

$g$  = Gravity [m/s<sup>2</sup>]

$c$  = Longitudinal distance between the vehicle's rear axle and its gravity center [m]

$$T_w^{eff} = \min \{T_w^{av}, T_{f(max)}\} \quad (11)$$

Due to the limiting factors described previously, the vehicle acceleration  $a_x$ , which can be expressed according to Equation 12, may be below the required acceleration  $a_{req}$ . In the case that actual vehicle acceleration  $a_x$  is inferior to the required one, the simulation carries out an iterative process, among Equations 6 to 12, in such a way that  $a_{req}$  is assumed equal to  $a_x$  until convergence. As a result of this, the greatest possible acceleration value is defined. Therefore, the effective engine output torque can be determined, as shown in Equation 13.

$$a_x = \frac{\frac{T_w^{eff}}{r} - R_x - D_A - W \sin(\theta)}{M} \quad (12)$$

$$T_{ICE}^{eff} = \frac{T_w^{eff} + \left( (I_e + I_t)(N_t N_d)^2 + I_d N_d^2 + I_w \right) \frac{a_x}{r}}{N_t N_d \eta_{td}} \quad (13)$$

Finally, the effective engine speed  $\omega_{ICE}^{eff}$  is given by Equation 14, as a function of the tire slip coefficient  $e$  (Figure 4), which varies according to the effective torque  $T_w^{eff}$ .

$$\omega_{ICE}^{eff} = \frac{N_d N_t V}{r(1 - e)} \quad (14)$$

## VEHICLE MODEL

In order to simulate the SS system influence on vehicle fuel consumption and exhaust emissions, a vehicle model is developed in Matlab/Simulink™ environment, added to the fuel converter block from ADVISOR™.

Figure 4 – Tire slip coefficient variation according to the effective traction torque

In this study, the model is based on a Brazilian vehicle equipped with a 1.0L 4-cylinder engine. Moreover, the standard gear shifting described in [42] was used as reference for the simulation model presented in this paper. The specification parameters of the vehicle are shown in Table 1.

Table 1 – Vehicle model's parameters

Parameters	Units	Gear				
		1 <sup>st</sup>	2 <sup>nd</sup>	3 <sup>rd</sup>	4 <sup>th</sup>	5 <sup>th</sup>
Engine inertia	kgm <sup>2</sup>	0.1367

## ENGINE MODEL

Once the engine operation point is determined according to the equations described previously, the fuel consumed and gas emissions should be determined. In order to do such analysis, this study uses the Advanced Vehicle Simulator (ADVISOR), which is a system-level simulation tool used for the evaluation of fuel consumption and exhaust emissions according to experimental database of vehicles running over standard driving cycles [43]. One of the advantages of ADVISOR™ is that it quantifies the tailpipe emissions taking into account the engine temperature, which influences on catalyst efficiency and, consequently, the results of those emission values [19].

Several works have used this vehicle simulation tool for fuel economy and gas emission analysis [44]–[48]. Thus, in this paper, the unburned hydrocarbons (HC), nitrogen dioxide (NOx) and carbon monoxide (CO) emissions are determined from the ADVISOR™ engine emission maps (shown in Figure 5), so that SS system effectiveness in reducing those indexes can be analyzed.

## DRIVING CYCLE

The vehicle model runs on the standard FTP-75 driving cycle (also NBR 6601 [49]), which is included an engine shutdown period to simulate cold and hot start phases, as illustrated by Figure 6.

In order to expand the analysis and compare results for different driving conditions, the simulation is also subject to a real-world driving cycle from Campinas city (shown in Figure 7), where the road altimetry is obtained by data acquisition and used for the determination of the road grade and calculation of the gravitational force acting on the vehicle (Figure 8) [50]. As traffic jam is one of the common issues found in large cities as Campinas, the SS system may be a very interesting alternative to reduce pollutant emissions and fuel consumption in this type of real-world driving scenario.

The driving cycle parameters of both cycles used in this study is presented by Table 2. It is possible to observe that the vehicle idling consists of a relevant fraction of both cycles and, consequently, of fuel consumed and generated tailpipe emissions.

Table 2 – Driving cycles' characteristics

Driving cycle parameters	FTP-75 (NBR 6601)	Real-world (Campinas)
Total distance [km]	17.79	45
Total time [s]	2500	7510
Average speed [km/h]	25.62	20.18
Idling time [%]	39.32	21.52
Maximum speed [km/h]	91.09	73.46

Figure 8 – Altimetry of Campinas driving cycle. Adapted from [46]

## START/STOP STRATEGY

With regards to the start/stop simulation model, a strategy that rules the actuation of the system was established, as expressed by Equation 15. The engine temperature  $C_{ICE}$  higher than 95 °C was introduced as one of the constraints for the engine shutdown since it avoids the postponement of the engine warmup period, which results in low-efficiency catalyst and, consequently, the increase in gas emissions [19]. The state variable  $E_{st}$  is 0 when the engine is switched off and 1 otherwise.

$$E_{st} = \begin{cases} 0, & \text{if: } T_{ICE}^{eff} = 0 \text{ and } V = 0 \text{ and } C_{ICE} \geq 95^\circ\text{C} \\ 1, & \text{otherwise} \end{cases} \quad (15)$$

In this work, the comparative analysis between the results of fuel economy and tailpipe emissions with and without such engine temperature restriction will be carried out in the following section. Furthermore, the minimum time of engine turned off was set as 7 seconds, which is the effective idle time (break-even point for fuel efficiency), proposed by [36], for a similar engine as the one presented in this study.

## SIMULATION RESULTS

The simulation was performed under the urban FTP-75 and Campinas drive cycles, as described previously. It will be evaluated three different conditions, which are the following: the baseline configuration (conventional vehicle); the conventional vehicle model subject to the actuation of the SS system according to the strategy described by Equation 15; and the conventional vehicle subject to SS strategy without engine temperature  $C_{ICE}$  constraint.

Since the SS system has more influence on urban traffic conditions that extend the engine warm-up period, the cold-start phase of FTP-75 will be analyzed separately from the rest of the cycle. In a similar approach, the Campinas cycle, which stands for typical real-world driving condition for crowded cities, is also investigated in a specific part of the route. Such condition is characterized by intense traffic jam, where fuel consumption and exhaust emissions are influenced by SS actuation.

## FTP-75 DRIVING CYCLE

As the number of engine stops increases during the driving cycle and the engine reaches its steady-state temperature, the SS system starts to achieve more relevant results regarding the reduction of exhaust emissions. Table 3 presents the results of pollutant emissions as well as fuel consumption for all the FTP-75 cycle. It is possible to see that the SS strategy with no  $C_{ICE}$  constraint still showed greater amount of emitted CO than baseline configuration. This is due to the fact that the CO emission during engine cold start represents the majority of air pollutants emitted [51]. The SS actuation with engine temperature analysis, on the other hand, achieved 8.92% fuel saving associated with 0.52% CO, 5.66% HC and 2.76% NO<sub>x</sub> emissions reduction. Thus, it is possible to infer that such engine-temperature-based SS strategy configuration presented the best performance with respect to the balance between fuel consumption and exhaust emissions.

Regarding the cold-start phase of FTP-75 driving cycle, the baseline configuration results for engine temperature and fuel consumption are depicted by Figure 9. During this engine start condition, it is possible to observe that the engine temperature restriction for the SS strategy development is critical to obtain better results with respect to air pollutant emissions. Despite the fuel economy improvement of 3.59%

Figure 9 – Engine temperature and fuel consumption for the standard vehicle under cold-start phase of FTP-75 cycle

Table 3 – FTP-75 cycle: emissions and fuel consumption results

Parameters	Conventional	SS	SS with no $C_{ICE}$
FC [l]	1.456	1.326	1.319
CO [g/km]	1.737	1.728	1.776
HC [g/km]	0.265	0.250	0.246
NO <sub>x</sub> [g/km]	0.181	0.176	0.178
Warm-up[s]	287	287	301

generated by SS strategy with no  $C_{ICE}$  condition, the CO and NO<sub>x</sub> emissions were increased by (3.50% and 1.24%), respectively, when compared to the conventional vehicle equipped with no SS system, as illustrated by Figure 10.

This is due to the extended engine warm-up period [19] (14 s more), which is caused by the higher number of engine shutdowns during the driving profile. Hence, one solution to address this concern is to include a limiting condition that prevents the engine turns off before it reaches its steady-state temperature (95 °C). Furthermore, Figure 11 shows that the all gas emissions' indexes are slightly lower than the conventional vehicle (0.1% CO, 0.36% HC, 0.31% NO<sub>x</sub>) when  $C_{ICE}$  constraint is introduced since the warm-up time is now the same as the conventional vehicle (287 s). The fuel consumption decreases 1.41% when compared to baseline configuration (425.1 ml against 431.2 ml) and increases 2.21% with regards to the SS strategy with no  $C_{ICE}$  condition (425.1 ml against 415.7 ml) as the engine turns off less often.

Figure 10 – Engine temperature and fuel consumption: SS system without  $C_{ICE}$  restriction under cold-start phase of FTP-75 cycle

Figure 11 – Engine temperature and fuel consumption: SS system with  $C_{ICE}$  restriction under cold-start phase of FTP-75 cycle

## CAMPINAS DRIVING CYCLE

In the second analysis, the vehicle model runs under Campinas cycle. This driving condition is different from the urban FTP-75 profile since there is no cold-start phase. In fact, there is only one vehicle stop (the approximate 20 s at the beginning of the cycle) until the engine reaches its steady-state temperature condition. For this reason, the standard vehicle idling occurs in a very short period of time and the engine warm-up time for the three cases analyzed in this paper are very similar to each other, as described by Table 4. Therefore, the SS strategy without  $C_{ICE}$  restriction presented lower emission indexes than the baseline configuration for the air pollutants evaluated (-1.19% CO, -3.61% NO<sub>x</sub> and -6.31% HC), while maximizing the fuel economy in 10.02%. Moreover, the SS system that considers  $C_{ICE}$  in its actuation strategy obtained increase of 9.79% in fuel economy as well as a decrease of 1.68% CO, 5.79% HC and 4.22% NO<sub>x</sub> emissions.

Table 4 – Campinas cycle: emissions and fuel consumption results

Parameters	Conventional	SS	SS with no $C_{ICE}$
FC [l]	3.952	3.565	3.556
CO [g/km]	1.010	0.993	0.998
HC [g/km]	0.190	0.179	0.178
NO <sub>x</sub> [g/km]	0.166	0.159	0.160
Warm-up[s]	336.4	336.4	337.2

## ENGINE START-UP AT TRAFFIC JAM CONDITION

In order to evaluate a possible cold-start phase for the Campinas driving profile, it is assumed that the vehicle starts to run from 1550s onwards as this part of the route consists of a low-speed driving profile (see Figure 7), which results in a long time of engine heating process. In this assumption, the engine starts at ambient temperature (20 °C).

For the three cases analyzed in this study, the engine temperature and fuel consumption curves along 1500 seconds (from 1550 s to 3050 s of the original driving cycle) are presented by Figure 12 (baseline), Figure 13 (SS actuation) and Figure 14 (SS actuation without  $C_{ICE}$  restriction). In this driving condition, the vehicle equipped with engine-temperature-based SS strategy achieved the improvement of 1.95% in fuel economy in comparison with the standard configuration, while reducing by 0.34% CO, 1.04% HC and 0.57% NO<sub>x</sub> emissions.

However, the SS strategy with no  $C_{ICE}$  constraint presented, as in the FTP-75 cold-start phase, higher CO and NO<sub>x</sub> emission indexes, that is, an increase of 3.41% and 7.02%, respectively. This is primarily related to the fact that the engine stops prevent its temperature to reach optimal condition (95 °C) quickly. In this case, the engine warm-up is only achieved in 1001 s, while the other configurations showed time of 817 s.

Figure 12 – Engine temperature and fuel consumption for the standard vehicle under hypothetical cold-start phase of Campinas cycle

Figure 13 – Engine temperature and fuel consumption for vehicle equipped with SS system with  $C_{ICE}$  restriction configuration under hypothetical cold-start phase of Campinas cycle

Figure 14 – Engine temperature and fuel consumption for vehicle equipped with SS system without  $C_{ICE}$  restriction configuration under hypothetical cold-start phase of Campinas cycle

## CONCLUSIONS

In this study, an engine start/stop system was modeled and simulated for a compact vehicle equipped with a 1.0L gasoline engine in order to investigate the efficacy of such technology. The vehicle model was developed in MATLAB/Simulink™ environment. The effects of SS system on fuel consumption and air pollutant emissions were evaluated under the FTP-75 (NBR 6601) and Campinas driving cycles using ADVISOR™ simulation tool. Furthermore, the SS strategy was modified by adding the engine temperature constraint, so that the system performance could be analyzed under engine cold start conditions. The SS system presented relevant results with respect to fuel saving in strategy modes with and without engine temperature condition. For engine-temperature-based

SS strategy mode, the fuel economy improvement under FTP-75 and Campinas cycle was 8.92% and 9.79%, respectively. The SS with no  $C_{ICE}$  constraint, on the other hand, reduced the standard vehicle fuel consumption by 9.40% (FTP-75) and 10.02% (Campinas cycle). Despite the better results with regards to fuel consumption, the SS-without-engine-temperature-restriction strategy mode showed performance issues related to its extended engine warm-up period as the vehicle runs on engine cold-start driving profiles, very common in traffic jam conditions. That resulted in low catalyst efficiency and, consequently, greater CO and NO<sub>x</sub> emissions. Therefore, the engine temperature proved to be an important parameter in the SS strategy development since the system can evaluate a more suitable moment to switch off the engine, balancing both fuel saving and tailpipe emissions. Finally, it can be concluded that

start/stop technology can be effective and the engine temperature is an important parameter to consider in the development of its strategy as it directly influences gas emissions. Its low cost and easy integration into vehicle system architecture is found to be a good alternative to provide greener and fuel-efficient vehicles, so pursued by modern governmental regulations worldwide. For future works, vehicle tests will be important to validate the simulation model, analyzing the real performance of the SS system.

## ACKNOWLEDGEMENT

This work was conducted during scholarships supported by the Brazilian Federal Agency for Support and Evaluation of Graduate Education (CAPES) and the University of Campinas (UNICAMP).
